Model

- Let us consider a mobile robot acting in 2D space
- Let us make no hypothesis on the driving system (two wheels, three wheels, four wheels, omnidirectional wheels, etc.)
- Let us consider the robot a **rigid body** with its mass center placed in the geometric center, e.g. a cylinder with uniform density

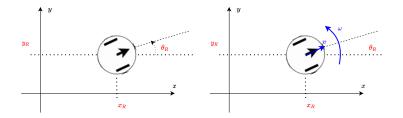

Cinematic Model

• From the cinematic point of view, the **pose** of the robot (**position**) is characterised by the 2D coordinates and the orientation:

$\{\mathbf{x}_{\mathsf{R}}, \mathbf{y}_{\mathsf{R}}, \mathbf{\theta}_{\mathsf{R}}\}$

 The robot's speed is characterised by the linear speed of the mass' center ν and the rotational speed of the body ω

ъ

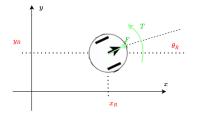

Cinematic Model

The following relations hold:

$$\begin{aligned} \dot{x}_{R}(t) &= v(t)\cos\theta(t) \\ \dot{y}_{R}(t) &= v(t)\sin\theta(t) \\ \dot{\theta}(t) &= \omega(t) \end{aligned}$$

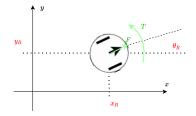

• where $\dot{x_R}(t)$ and $\dot{y_R}(t)$ the component of the linear speed v along x and y axis

Dynamic Model

From the dynamic point of view, we consider that the driving system is able to apply:

- A force F to the mass' center
- A torque T for rotation along the vertical axis passing from the mass' center

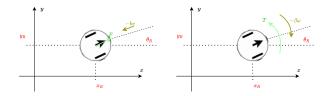

Dynamic Model

To model the physics of a rigid body, we must consider the second Newton's law in both linear and rotational aspects:

- Linear: $\sum F_i = Ma = M\dot{v}$
- **Rotational:** $\sum T_i = I\dot{\omega}$ where
 - T_i is the *i*th torque applied
 - I is the moment of inertia
 - *ώ* is the angular acceleration

(See https://en.wikipedia.org/wiki/List_of_moments_of_inertia)

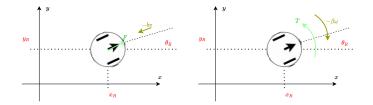

Dynamic Model

 $F - bv = M\dot{v}$ $T - \beta\omega = I\dot{\omega}$

where β is the rotational friction coefficient

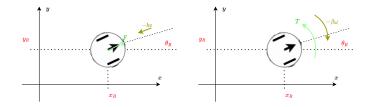

Since $I = \frac{1}{2}Mr^2$ for a cylindric robot, we have:

$$F - bv = M\dot{v}$$
$$T - \beta\omega = \frac{1}{2}Mr^{2}\dot{\omega}$$

Dynamic Model

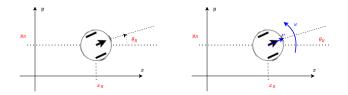

$$\dot{\mathbf{v}} = -\frac{b}{M}\mathbf{v} + \frac{1}{M}F$$
$$\dot{\omega} = -\frac{2\beta}{Mr^2}\omega + \frac{2}{Mr^2}T$$

Dynamic Model

$$\begin{bmatrix} \dot{\mathbf{v}} \\ \dot{\omega} \end{bmatrix} = \begin{bmatrix} -\frac{b}{M} & \mathbf{0} \\ \mathbf{0} & -\frac{2\beta}{Mr^2} \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \omega \end{bmatrix} + \begin{bmatrix} \frac{1}{2} & \mathbf{0} \\ \mathbf{0} & \frac{2}{Mr^2} \end{bmatrix} \begin{bmatrix} \mathbf{F} \\ \mathbf{T} \end{bmatrix}$$

It is a linear system with two inputs

Model Discretization

$$v(k+1) = v(k) - \frac{b\Delta T}{M}v(k) + \frac{\Delta T}{M}F(k)$$

$$\omega(k+1) = \omega(k) - \frac{2\beta\Delta T}{Mr^2}\omega(k) + \frac{2\Delta T}{Mr^2}T(k)$$

$$x_R(k+1) = x_R(k) + v(k)\Delta T\cos\theta(k)$$

$$y_R(k+1) = y_R(k) + v(k)\Delta T\sin\theta(k)$$

$$\theta(k+1) = \theta(k) + \omega(t)\Delta T$$

Implementing the Cart in 2D

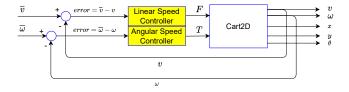

The Code

```
class Cart2D:
    def __init__(self, _mass, _radius, _lin_friction, and friction):
        self.M = mass
        self.b = lin friction
        self.beta = ang friction
        self.Iz = 0.5 * mass * radius * radius
        # Iz = moment of inertia (the robot is a cylinder)
        self.v = 0
        self w = 0
        self x = 0
        self.y = 0
        self theta = 0
    def evaluate(self, delta_t, _force, _torque):
        new v = self.v * (1 - self.b * delta t / self.M)
                + delta t * force / self.M
        new w = self.w \star (1 - self.beta \star delta t / self.Iz) \
                + delta t * torque / self.Iz
        self.x = self.x + self.y * delta t * math.cos(self.theta)
        self.y = self.y + self.y * delta t * math.sin(self.theta)
        self.theta = self.theta + delta t * self.w
        self v = new v
        self w = new w
```

◆□▶ ◆□▶ ◆ □▶ ◆ □ ● ● の Q @

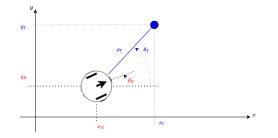

Controlling the Speed

Speed Control in a 2-Dimensional Space

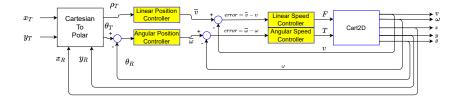

- Controlling the speed is quite straightforward
- v and ω are independent
- v depends only on F
- ω depends only on T
- We can use two independent speed controllers, one for each speed
- They can also be tuned independently

Controlling the Position

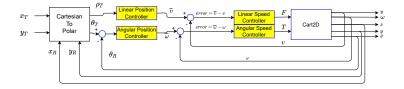

- Let us consider a robot with pose $\{x_R, y_R, \theta_R\}$
- We want the robot reach position $\{x_T, y_T\}$
- The theoretical trajectory is the blue line
- So we can consider two different targets
 - The distance ρ_T
 - The heading θ_T
- And we want to control both simultaneously

We can consider

- ρ_T as a distance error
- The heading difference $\theta_T \theta_R$ as the heading error
- ρ_T can drive a linear position controller giving the target v
- $\theta_T \theta_R$ can drive a linear angular controller giving the target ω

< □ > < □ >

Cartesian to Polar

$$\rho_T = \sqrt{(x_T - x_R)^2 + (y_T - y_R)^2}$$

$$\theta_T = \arctan \frac{y_T - y_R}{x_T - x_R}$$

$$\theta_{error} = \theta_T \ominus \theta_F$$

The Sign of the Distance

$$\rho_T = \sqrt{(x_T - x_R)^2 + (y_T - y_R)^2}$$

$$\theta_T = \arctan \frac{y_T - y_R}{x_T - x_R}$$

$$\theta_{error} = \theta_T \ominus \theta_R$$

- According to the formula above, the distance is always positive
- But, what does it happen if the robot overcomes the target?
- We expect that the distance becomes negative, but, with those formulas, this is not the case!
- We can instead use the **heading error**: if the target (and thus θ_{error}) is in the second or third quadrant, the target is **behind** the robot, and we can change:
 - The sign of ρ_T
 - θ_T by adding π

(See Polar2DController in libs/controllers/control2d.py)

Implementing the Polar Controller

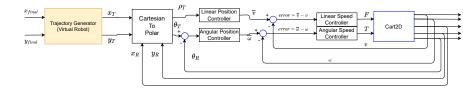

lib/controllers/control2d.py

```
class Polar2DController:
   def init (self, KP linear, v max, KP heading, w max):
        self.linear = PIDSat(KP linear, 0, 0, v max)
        self.angular = PIDSat(KP heading, 0, 0, w max)
   def evaluate(self, delta t, xt, yt, current pose):
        (x, y, theta) = current_pose
       dx = xt - x
       dy = yt - y
        target heading = math.atan2(dy, dx)
        distance = math.sqrt(dx*dx + dy*dy)
        heading error = normalize angle(target heading - theta)
        if (heading error > math.pi/2) or (heading error < -math.pi/2):
            distance = -distance
            heading error = normalize angle(heading error + math.pi)
       v target = self.linear.evaluate error(delta t, distance)
        w target = self.angular.evaluate error(delta t, heading error)
        return (v target, w target)
```

= 990

Following a Trajectory

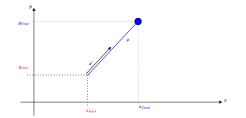

Following a Trajectory

- The polar control uses two P controllers to control position, therefore it does not give the possibility to specify acceleration or deceleration ramps
- In these cases, a trajectory generator can be used to give the (moving) target position (virtual robot) that has to be reached time-by-time by the (real) robot

Image: A matrix

Following a Trajectory

- Let us consider the robot in the initial position {*x*_{start}, *y*_{start}} and that we want to reach position {*x*_{final}, *y*_{final}} using a straight line
- We can consider a change in the reference frame with the x' along the straight line and a virtual robot moving along such a line
- The 1D-virtual robot algorithm gives the position x'(t) of the virtual robot at time instant t
- Then it is roto-translated to the {x, y} frame thus generating the couple {x_T, y_T} to be provided to the Polar Controller

Implementing Virtual Robot in 2D

lib/controllers/control2d.py

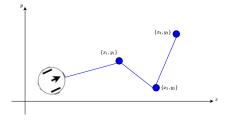

```
class StraightLine2DMotion:
   def init (self, vmax, acc, dec):
        self.vmax = vmax
        self.accel = acc
        self.decel = dec
   def start motion(self, start, end):
        (self.xs, self.ys) = start
        (self.xe, self.ye) = end
       dx = self.xe - self.xs
       dy = self.ye - self.ys
        self.heading = math.atan2(dv, dx)
        self.distance = math.sqrt(dx*dx + dy*dy)
        self.virtual robot = VirtualRobot(self.distance,
                                  self.vmax, self.accel, self.decel)
   def evaluate(self, delta t):
        self.virtual robot.evaluate(delta t)
       xt = self.xs + self.virtual_robot.p * math.cos(self.heading)
       yt = self.ys + self.virtual_robot.p * math.sin(self.heading)
        return (xt, yt)
```

Using the Virtual Robot in 2D

tests/cart_2d/test_robot_trajectory.py

```
class Cart2DRobot(RoboticSvstem):
  def __init__(self):
      super().__init__(1e-3) # delta_t = 1e-3
      # Mass = 1kg, radius = 15cm, friction = 0.8
      self.cart = Cart2D(1, 0.15, 0.8, 0.8)
      self.linear speed controller = PIDSat(10, 3.5, 0, 5) \# 5 newton
      self.angular speed controller = PIDSat(6, 10, 0, 4)
      self.polar_controller = Polar2DController(0.5, 2, 2.0, 2)
      self.trajectory = StraightLine2DMotion(1.5, 2, 2)
      (x, y, _) = self.get_pose()
      self.trajectory.start motion((x,y), (0.5, 0.2))
  def run(self):
      (x_target, y_target) = self.trajectory.evaluate(self.delta_t)
      (v target, w target) = self.polar controller.evaluate(self.delta t,
                                     x_target, y_target, self.get_pose())
      Force = self.linear speed controller.evaluate(self.delta t,
                                                   v target, self.cart.v)
      Torque = self.angular speed controller.evaluate(self.delta t,
                                                   w target, self.cart.w)
      self.cart.evaluate(self.delta t, Force, Torque)
      return True
```

Following a More Complex Trajectory

- But if we want to follow a generic path?
- A basic solution is to split the path into a sequence of segments and follow each segment
- Once an intermediate point is reached, we start following the next segment
- However, in checking the arrival to a point, a threshold is always needed

The Path Follower 2D

lib/controllers/control2d.py

```
class Path2D:
   def init (self, vmax, acc, dec, threshold):
        self.threshold = threshold
        self.path = [ ]
        self.trajectory = StraightLine2DMotion(vmax, acc, dec)
   def set_path(self, path):
        self.path = path
   def start(self, start pos):
        self.current target = self.path.pop(0)
        self.trajectory.start motion(start pos, self.current target)
   def evaluate(self, delta_t, pose):
        (x, y) = self.trajectory.evaluate(delta t)
        target_distance = math.hypot(pose[0] - self.current_target[0],
                                     pose[1] - self.current_target[1])
        if target_distance < self.threshold:
            if len(self.path) == 0:
                return None
            else:
                self.start( (x,y) )
        return (x,y)
```

-22

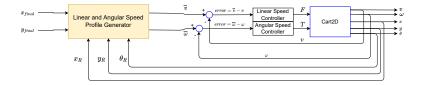

Using the Path Follower

tests/cart_2d/test_robot_path.py

```
class Cart2DRobot (RoboticSystem) :
```

```
def init (self):
    super().__init__(1e-3) # delta_t = 1e-3
    self.cart = Cart2D(1, 0.15, 0.8, 0.8)
    self.linear speed controller = PIDSat(10, 3.5, 0, 5) # 5 newton
    self.angular speed controller = PIDSat(6, 10, 0, 4) # 4 newton * metro
    self.polar controller = Polar2DController(0.5, 2, 2.0, 2)
    self.path_controller = Path2D(1.5, 2, 2, 0.01) # tolerance 1cm
    self.path controller.set path( [ (0.5, 0.2),
                                     (0.5, 0.4),
                                     (0.2, 0.2) ])
    (x, y, _) = self.get_pose()
    self.path controller.start( (x,v) )
def run(self):
    target = self.path controller.evaluate(self.delta t,
                                           self.get pose())
    if target is None:
        return False
    (x target, v target) = target
    (v target, w target) = self.polar controller.evaluate(self.delta t, x ta
    Force = self.linear speed controller.evaluate(self.delta t, v target, se
    Torque = self.angular speed controller.evaluate(self.delta t, w target,
    self.cart.evaluate(self.delta t, Force, Torque)
    return True
```

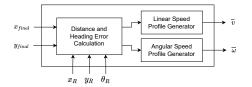

Following a Speed Profile

- Similarly to the 1-D case, we can generate the *v* and *w* directly from distance and heading errors
- This implies merging the Trajectory Generator, Cartesian-To-Polar and Position Controllers into a unique control block

< 一型

Following a Speed Profile

- Starting from the comparison between the target and the pose, the distance and the heading error are computed
- They are then passed to the two blocks that (according to the error) generate the proper speed using the trapezoidal profile

(See class **SpeedProfileGenerator2D** in **lib/models/virtual_robot.py** and **tests/cart_2d/test_robot_speed_profile.py**)
